Measuring and optimizing the influence of nodes in big-data online social networks are important for many practical applications, such as the viral marketing and the adoption of new products. As the viral spreading on a social network is a global process, it is commonly believed that measuring the influence of nodes inevitably requires the knowledge of the entire network. Using percolation theory, we show that the spreading process displays a nucleation behavior: Once a piece of information spreads from the seeds to more than a small characteristic number of nodes, it reaches a point of no return and will quickly reach the percolation cluster, regardless of the entire network structure; otherwise the spreading will be contained locally. Thus, we find that, without the knowledge of the entire network, any node’s global influence can be accurately measured using this characteristic number, which is independent of the network size. This motivates an efficient algorithm with constant time complexity on the long-standing problem of best seed selection, with performance remarkably close to the true optimum.

Modern online social platforms are replacing traditional media (1) for the spreading of information and communication of opinions (2–6). A common feature of today’s online social networks (OSNs) is their gigantic sizes—for example, as of the second quarter of 2016, there are about 1.5 billion monthly active users on Facebook. Notably, multiplicative explosions of some information may take place at a global scale in such gigantic OSNs, which is the foundation of viral marketing strategies (7). Because of this, quantification of viral spreading is traditionally believed to need global network information. Indeed, most measures, such as k-shell (2), degree discount (8), cost-effective lazy forward (9), betweenness (10), closeness (11), and Katz index (12), evaluate the influence of nodes based on the knowledge of global network structures. In general, these methods become impractical for giant OSNs, because either the full network structural data are unavailable or the computational time is nonscalable. On the other hand, based on massive social experiments, Christakis and Fowler (13, 14) proposed the so-called three degrees of influence (TDI) theory, which states that any individual’s social influence ceases beyond three degrees (friends’ friends’ friends) and therefore suggests the existence of an unknown yet local effect. A recent study also shows that a local approximation works fairly well for a qualitative global measure of collective influence (4). The above situation reveals an apparent paradox, which inspires us to ask a fundamental question: Could local network structure accurately determine the size of global spreading?

Results

Here we recover a local characteristic infection size $s^*$ of the spreading process. It determines the key influence size in the stochastic spreading process described by the susceptible–infected–recovered (SIR) family models (15–21), which well describe the information spreading process in social media (22–25). We find a ubiquitous and well-separated, bimodal behavior in the supercritical spreading regime—the spreading either extends globally, reaching a finite fraction of the total population irrespective of the initial condition, or diminishes quickly beyond the local characteristic infection size (Fig. 1 A and C). The global and local phases are unambiguously separated. Using the mapping between the SIR family model and bond percolation (18, 26), we provide a concrete physical understanding of these two well-separated phases. We show that the local phase can be used to accurately quantify the node’s (or nodes’) spreading power (Fig. 2A). In particular, the statistical properties of infected cluster size distribution allow us to use solely local network structural information for selecting the best seed spreaders in significantly short constant time complexity.

Methods

Our study is carried out for an SIR spreading mechanism on connected networks. The central quantity of interest in the spreading model is the final number of activated nodes or the spreading influence (17). A common definition of the spreading influence of node $i$ is the expected number of active nodes that originated from $i$,

$$\sum_{s=1}^{N} s g(i, s),$$

where $g(i, s)$ is the number of nodes in state $s$ infected by node $i$. This article contains supporting information online at www.pnas.org/lookup/suppl/doi:10.1073/pnas.1710547115/-/DCSupplemental.

Significance

Identification and quantification of influential spreaders in social networks are challenging due to the gigantic network sizes and limited availability of the entire structure. Here we show that such difficulty can be overcome by reducing the problem scale to a local one, which is essentially independent of the entire network. This is because in viral spreading the characteristic spreading size does not depend on network structure outside the local environment of the seed spreaders. Our approach may open the door to solve various big data problems such as false information surveillance and control, viral marketing, epidemic control, and network protection.

where \( g(i, s) \) is the probability that a total of \( s \) nodes are eventually activated by node \( i \) in a network of \( N \) nodes, and the probability of an active node to activate a neighboring node is \( \beta \). In information spreading, an activated node corresponds to a spreader. We find that the probability distribution function \( g(i, s) \) has two prominent features: (i) it consists of two peaks, which correspond to local and viral spreadings. The local peak is located at small \( s \), while the viral peak is centered at significantly larger \( s \) (Fig. 1 A and C). Furthermore, the viral peak is a \( \delta \)-like function, whose location is independent of node \( i \) and different stochastic realizations (SI Appendix, section II). (ii) The two peaks are separated by a wide gap, which implies that one may introduce a small filtering size, \( s^* \), to distinguish between the two phases.

The statistical properties underlying these two features can be explored and better understood using the framework of percolation theory. This can be done through mapping the SIR process to bond percolation (18, 19), where every link (bond) has a probability 1 — \( \beta \) to be removed from the network (see SI Appendix, section XII for the more general case where \( \beta \) is link dependent). The final network forms many connected clusters of different sizes. It has been proved that the probability distribution function \( g(i, s) \) in Eq. 1 is exactly equivalent to the cluster size distribution function \( p(s) \), where \( s \) is the size of the cluster that node \( i \) belongs to (18, 27, 28). According to percolation theory, a giant component of size \( s^\infty \) emerges above the percolation transition threshold \( \beta_c \) (Fig. 1B), where \( p(s, \beta) \) is split into a finite (nongiant) part \( p(N, s) \) and a giant part \( p(s, \infty) \) (Fig. 1C). The size of \( s^\infty \) is proportional to \( N \) and depends on \( \beta \). Because \( \sum s p_s (i, s) \ll s^\infty p(s, \infty) \), we may approximate Eq. 1 as

\[
S(i) \approx \bar{S}(i) \equiv s^\infty p(s, \infty),
\]

where \( s^\infty = \sum_{i=1}^{N} p_s(i, \infty) \). In other words, the spreading power of one node is the product of the giant component size and the probability that this node is in the giant component. In information spreading, a broader type of definition for “influence” exists by including the nodes that are linked to the spreaders but do not spread the information further, called “listeners” (29). Since the underlying two-phase behavior is essentially the same, the total number of listeners and spreaders increases monotonically with the total number of spreaders approximated in our percolation-based algorithm. This implies that maximizing the influence including listeners is equivalent to the problem of maximizing the number of spreaders (SI Appendix, section III).

In artificial random networks with structure purely determined by the degree distributions, we can give the analytical solution for this influence quantity \( \bar{S}(i) \) in Eq. 1, with

\[
p_s(i, s^\infty) = 1 - (1 - q^i)^s,
\]

where \( q^i \) is the degree of node \( i \), and \( s^\infty = N \sum_{i=1}^{N} p_s(i, \infty) \). Here, \( q \) is the probability of a random link to be connected to the giant component and is determined from the self-consistent equation \( q = \beta \sum_{i=1}^{N} p_s^{\infty}(i) [1 - (1 - q^{i-1})^s] \), with average degree \( k \) and arbitrary degree distribution \( P_k(i) \) (30). The theoretical considerations and details for undirected, directed, and degree-degree correlated are presented in SI Appendix, sections IV and V.

For real networks whose structures are much more complex than random networks, an exact solution to the spreading influence is not possible. But the critical phenomenon and the statistical properties of the two phases remain the same (Fig. 1C). We can leverage on these properties, in particular the wide gap between these two phases to distinguish between viral and local spreadings, and construct methods to estimate the spreading influence of nodes in the network. In SIR processes, once the number of activated nodes reaches a threshold parameter \( m \), the simulation could be terminated since this process is known to become most likely viral. We thus obtain a second approximated form for the node spreading power—the truncated spreading power,

\[
\bar{S}(i) \approx \bar{S}(i) \equiv s^\infty \bar{p}(i, s^\infty),
\]

where \( \bar{p}(i, s^\infty) \equiv \sum_{s=1}^{N} p_s(i, s) \), and \( s^\infty \equiv \sum_{i=1}^{N} \bar{p}(i, s^\infty) \). It turns out that percolation theory provides a fundamental insight into determining the threshold value \( m \). According to the theory, the distribution \( p_s(i, \beta) \) has a fast decay tail \( e^{-m/s^\infty} \), where \( s^\infty \) gives a characteristic size of the finite components (27, 31). For any \( m \geq s^\infty \), the error introduced in \( \bar{S}(i) \) by truncating this tail is small (see Fig. 2A for a comparison between the real \( S(i) \) and \( \bar{S}(i) \) in real networks). Fig. 2B shows that the relative error \( E'(i, m) \equiv |S(i) - \bar{S}(i)|/\bar{S}(i) \) decays quickly with \( m \) and becomes negligible for \( m \geq s^\infty \) (see SI Appendix, sections IV and V for a theoretical calculation of the error in random networks). Similar to the giant component size, the characteristic component size \( s^\infty \) is intrinsic to the whole network and independent of the seed node \( i \). Hence the characteristic size \( s^\infty \) has an important implication: Once it is determined either theoretically or numerically, it can be used as a threshold for the parameter \( m \). As long as \( m \) is chosen to be above \( s^\infty \), the truncated
This behavior is analogous to a critical point. The m dependence of the relative error $E(t, m)$ of nodes whose degrees are equal to the average degree $\langle k \rangle$, in the NOLA Facebook ($\beta = 0.02$) network. (B, inset) The $m$ dependence of the relative error $E(t, m)$ of nodes with different degrees. The relative error decreases quickly with $m$ and becomes smaller than $1\%$ when $m > s^*$. Comparing among influence radius $s^*$, the average distance of the farthest nodes from the seed nodes $s_{\text{far}}$, and the network diameter $D$ in nine OSNs and two random networks (an ER network with $N = 50,000$, $k = 10$ and a scale-free (SF) network with $N = 50,000$, $k(k) \sim k^{-2.7}$). We choose $\beta$ in different networks such that the fraction of the giant component is the same; i.e., $s^* = 0.3N$ (see SI Appendix, section I for the real networks description). (D) The NOLA Facebook influence radius $i^*$ is smaller than both $s_{\text{far}}$ and $D$ for any $\beta > \beta_c$.

spreading power $S(i)$ is an excellent approximation for $S(l)$, and its error is well controlled (SI Appendix, section VI).

The average of the cluster size distribution, $p(i, s)$, from seed node $i$ gives the global cluster distribution function $p(s) = \frac{1}{i} \sum_{i=1}^{N} p(i, s)$. Excluding the giant component, its finite part $p_0(s)$ has the same tail as that of $p(i, s)$ ($26, 27, 32$) (Fig. 1D).

$$p_0(s) \sim s^{-1} e^{-s^*/s}$$  \hspace{1cm} [5]

which can be used to obtain $s^*$ theoretically in random networks ($27$). For example, in an Erdős-Rényi (ER) network, we obtain $s^*_{\text{ER}} = 3.9N^{\beta_c-\frac{1}{2}}$ ($\beta_c = 0.5$) (SI Appendix, section IV). An expansion of this expression around the percolation transition $\beta_c$ gives the critical scaling $s^* \sim |\beta - \beta_c|^{-1/\nu_c}$ with the mean-field exponent $\nu_c = 0.5$. For real OSNs, $s^*$ is obtained by fitting the simulation data to the exponential tail in Eq. 5 (Fig. 1D and SI Appendix, section VII). Fig. 1D, inset shows that $s^*$ in real Facebook OSN also satisfies the critical power-law scaling.

To reveal the topological meaning of the characteristic size $s^*$, we define an influence hopping radius $i^*$ associated to $s^*$. We perform SIR simulations until $s^*$ nodes are activated and assign the maximum hopping distance (shortest path) between the seed and active nodes, averaged over all realizations and nodes, to be the influence radius $i^*$. For a typical $\beta$ such that $s^* = 0.3N$, we find that $i^* \sim 3 - 4$ in all OSNs studied, which is significantly smaller than the average distance and diameter of the network as shown in Fig. 2C. This result shows that if an SIR spreading is local, then it would vanish within three to four steps; otherwise, it will spread to about $s = 0.3N$ nodes. Note that $i$ increases when $\beta \to \beta_c$ (Fig. 2D), whose scaling is discussed in SI Appendix, section IV. This behavior is analogous to a critical phenomenon of a continuous phase transition: At the critical point, the correlation length diverges, but as long as it moves beyond the critical point, a characteristic scale appears.

The above analysis explains the following paradox: While it is shown that the information spreading is in general a global process due to the viral spreading in the supercritical phase, the influence of any node basically depends only on its local network environment. While the computation time for $S(i)$ in Eq. 1 grows linearly with $N$, it is reduced to an $N$-independent constant $O(m)$ for the truncated spreading power $S(i)$ in Eq. 4. An important extension of this finding is that the method can be combined with many search algorithms for detecting the best spreaders and reduce their time complexity by one order of $N$.

Next, we aim to find the best $M$ spreaders $V = \{v_1, v_2, \ldots, v_M\}$ from a given set $W$ of $L$ candidates, to maximize their collective spreading power $S(V) = \sum_{i=1}^{M} s(p(V, s)$, where $p(V, s)$ is the probability that a total of $s$ nodes are activated by the selected spreaders in $V$. Because it is usually more cost-effective to target a large set of less influential nodes, rather than a small set of globally most influential nodes (33), we choose nodes with average properties (around average degree) as candidates. In practice, it is usually extremely difficult to obtain the full network structural information. Therefore, unlike many other studies which select best seeds from the whole network, we only focus on a subset of candidate nodes. Extending from the formulation of a single node spreading power $S(i)$, we introduce a truncated collective spreading power $S(V) = \sum_{i=1}^{M} s(p(V, s)$, the probability that at least one cluster of at least $m$ nodes are activated by the $M$ seed spreaders. While the computation time for the collective influence $S(V)$ increases linearly with $N$ given any $V$, it becomes $N$-independent for the estimator $\tilde{S}(V)$.

Now we demonstrate one example of how to improve other algorithms and introduce quantification capabilities through the combination of our approach with the natural greedy algorithm (NGA) (8, 17). We call this algorithm the percolation-based greedy algorithm (PBGA). We (i) first find the best spreader $v_1$ with the maximal individual spreading power based on the estimator $\tilde{S}(v_1)$, (ii) then fix $v_1$ and find the second best spreader $v_2$ that maximizes the collective spreading power $S(V')$ for $V' = \{v_1, v_2\}$, and (iii) repeat this process $M$ times until $M$ spreaders $V = \{v_1, v_2, \ldots, v_M\}$ are selected. As a greedy algorithm, the PBGA maximizes the marginal gain in the objective function $s(V)$ at each step. Note that replacing the objective function by the real spreading power in the above procedure would basically recover the NGA (see SI Appendix, section IX for more details).

As expected, the simulation results show that the computational time in terms of execution count of PBGA is independent of network size $N$ (Fig. 3). This reduction becomes significant for a worldwide online social network with billions of nodes. In SI Appendix, Table 1, we compare and summarize the theoretical time complexities of our PBGA, the NGA, and other widely used algorithms, including brute-force search, genetic algorithms, and other heuristics.
Algorithm performance on real online social networks. For (A) NOLA Facebook ($\beta = 0.012$) and (B) Macau Weibo ($\beta = 0.055$) networks, we compare the algorithm performance of the PBGA with that of other algorithms: brute-force search (BFS), degree discount heuristic (DDH) (8), eigenvector method (EM), genetic algorithm (GA), maximum betweenness (MB) (10), maximum closeness (MC) (11), maximum degree (MD), maximum Katz (MK) index (12), maximum k-shell (MKS) (2), NGA, and MCI (4). The candidate nodes are randomly selected from the nodes with median degree nodes: Degree is 10 for nodes in Facebook and out-degree is 3 for nodes from Weibo. Since the candidate nodes have the same degree, the MD method is equivalent to the random selection of seed nodes. $S(V)$ is normalized by dividing the giant component size $s^\infty$. Here $L = 100$ candidates and $M$ varies from 1 to 100. (A and B, Insets) The regime $1 \leq M \leq 6$ is enlarged, where the rigorous optimum obtained from BFS is available. (C) On the Facebook network, the combined rigorous lower bound $\text{PR}_{\text{submod}}$ and the approximated lower bound $\text{PR}_{\text{approx}}$ are plotted together with the submodular lower bound $\text{PR}_{\text{submod}} = 0.63$ (17), as functions of $M$. (D) The relative performance between the PBGA solution based on $\beta = 0.02$ ($\beta = 0.05$) and the PBGA solution based on the other $\beta$ values, with both performances $V_1$ and $V_2$ estimated upon the same spreading rate $\beta$. The solid symbols (blue star and red diamond) label the performance of 1 when $\beta = \beta_0$. We see that as long as $\beta > \beta_0$, the solution at $\beta_0$ can be used at $\beta$ since their performances are almost the same, as long as both $\beta_0$ and $\beta$ are larger than the critical point $\beta_c \approx 0.01$.

Another important aspect of this maximization problem is to have a sense of how good the solution is compared with the true optimal solution $V^*$, which is usually unknown (9, 17). We give two lower bounds of the performance ratio $\text{PR} = S(V)/S(V^*)$ between the PBGA performance $S(V)$ and the exact optimal performance $S(V^*)$ (Fig. 4C): (i) a combined bound $\text{PR}_{\text{submod}} = \max\left\{\frac{\mu(V^*)}{\mu(V)}, \frac{\mu(V^*)}{\mu(V)}\right\}$, where $i\in^*$ is the set of $M$ nodes with the maximum individual probability $p_i(s^\infty)$ (it is rigorous for any networks), and (ii) an approximated bound $\text{PR}_{\text{approx}} \approx \frac{\mu(V^*)}{\mu(V)}$ that becomes rigorous in random networks (SI Appendix, section X). The rigorous bound $\frac{\mu(V^*)}{\mu(V)}$ and $\frac{\mu(V^*)}{\mu(V)}$ both work well in the small and large $M$ limits, respectively, where they both approach one, and the approximated bound $\text{PR}_{\text{approx}} \approx 1$ for any $M$ value considered. Considering the above discussion, we argue that the PBGA gives a nearly optimized solution for an arbitrarily given number $M$ of spreaders.

In practical situations, the information spreading rate $\beta$ is usually unknown. However, our PBGA method could find close to optimal solutions without knowing the exact $\beta$ value, as long as the information spreading is viral, i.e., a supercritical region with $\beta > \beta_c$ (see SI Appendix, section XI) for the nonviral subcritical regions $\beta < \beta_c$. As illustrated in Fig. 4D, the solutions found at an arbitrary spreading rate $\beta_0$ perform nearly optimally at higher spreading rate $\beta > \beta_0$. Thus, without knowing the exact spreading rate, one can use a spreading rate slightly above the critical value $\beta_0$, such that the solutions perform optimally at higher $\beta$ values. On a related note, it has been observed that information spreading could exhibit bursty behaviors with different spreading speeds (29). Such mechanism could be mapped to dynamics having different beta values over the course of spreading.
Fig. 5. Performance comparison between the PBGA and MCI. The vertical axis is the ratio between the seeds’ influence of the PBGA and MCI. For a small number $M$ of seed nodes, the PBGA significantly outperforms MCI. The difference diminishes as $M$ increases, when both solutions approach the theoretical maximum of giant component size. The simulation is carried out on the Facebook network with $\beta = 0.012$.

Summary

In this work, we show from first principles that any node’s influence can be quantified purely from its local network environment, based on the nature of the spreading dynamics. Our approach is distinct from other local attempts, which usually use some distance truncation strategies to approximate a relative global measure without the ability to quantify the actual influence. Although our framework is demonstrated on the basic SIR model, its applicability can be extended to several other spreading models if the following two properties hold: (i) For a collection of seed spreaders, the final steady states have two different outcomes of being either a localized outbreak with a small and finite number of infections or a global epidemic with the infectious/recovered population being proportional to the network size. (ii) When it is in the global outbreak, the size of the influence does not correlate with that of the initial spreader. See SI Appendix, section XII for discussions on a more general family of SIR models as well as for more complex models that include stiflers (34) and the susceptible–infect–susceptible model (22).
