The distribution of the return intervals \( \tau \) between price volatilities above a threshold height \( q \) for financial records has been approximated by a scaling behavior. To explore how accurate is the scaling and therefore understand the underlined nonlinear mechanism, we investigate intraday data sets of 500 stocks which consist of Standard & Poor’s 500 index. We show that the cumulative distribution of return intervals has systematic deviations from scaling. We support this finding by studying the \( m \)-th moment \( \mu_m = \langle (\tau/\langle \tau \rangle)^m \rangle^1/m \), which show a certain trend with the mean interval \( \langle \tau \rangle \). We generate surrogate records using the Schreiber method, and find that their cumulative distributions almost collapse to a single curve and moments are almost constant for most ranges of \( \langle \tau \rangle \). Those substantial differences suggest that nonlinear correlations in the original volatility sequence account for the deviations from a single scaling law. We also find that the original and surrogate records exhibit slight tendencies for short and long \( \langle \tau \rangle \), due to the discreteness and finite size effects of the records, respectively. To avoid as possible those effects for testing the multiscaling behavior, we investigate the moments in the range \( 10 < \langle \tau \rangle \leq 100 \), and find that the exponent \( \alpha \) from the power law fitting \( \mu_m \sim \langle \tau \rangle^{\alpha} \) has a narrow distribution around \( \alpha \neq 0 \) which depends on \( m \) for the 500 stocks. The distribution of \( \alpha \) for the surrogate records are very narrow and centered around \( \alpha = 0 \). This suggests that the return interval distribution exhibits multiscaling behavior due to the nonlinear correlations in the original volatility.

I. INTRODUCTION

The price dynamics of financial markets has long been a focus of economics and econophysics research [1–9]. Studying the volatility time series is not only crucial for revealing the underlined mechanism of financial markets dynamics, but also useful for traders. For example, it helps traders to estimate the risk and optimize the portfolio [8,10]. The volatility series is known to be long-term power-law correlated [11–22]. To better understand these correlations and characterize temporal scaling features in volatilities, recently Yamasaki et al. [23] and Wang et al. [24,25] studied the statistics of return intervals \( \tau \) between volatilities that are above a given threshold \( q \), which is an alternative way to analyze long-term correlated time series (see Ref. [26] and references therein). They find that scaling and memory in the return intervals of daily and intraday financial records are similar to that found in the climate and earthquake data [27–29]. Very recently, some related studies on financial markets, such as escape time [30], exit time [31,32], first passage time [32,33], and level crossing [34], have been performed.

Studies of financial records show that the scaling in the return intervals distribution can be well approximated by a scaling function [23–25]. However, financial time series are known to show complex behavior and are not of uniscaling nature [35] and nonlinear features [36]. Recent studies [37–39] of stock markets show that the distribution of activity measure such as the intertrade time has multiscaling behavior. Thus a detailed analysis of the scaling properties of the volatility return intervals is of interest. It might improve our understanding of the return intervals statistics and shed light on the underlined complex mechanism of the volatility. Our analysis suggests that for all Standard & Poor’s index constituents, the cumulative distributions of the return intervals depart slightly but systematically from a single scaling law. We also find that the moments \( \mu_m = \langle (\tau/\langle \tau \rangle)^m \rangle^1/m \) are consistent with the deviations from scaling. However, using the corresponding surrogate records [40–42] which remove the nonlinearities, \( \mu_m \) almost does not depend on \( \langle \tau \rangle \) and no deviation from scaling occurs. Therefore our results suggest that nonlinear correlations in the volatility account for the deviations from a scaling law.

The paper is organized as follows: In Sec. II we introduce the database and define the volatility. In Sec. III we discuss the scaling and investigate the deviations from scaling in the cumulative distributions of the return intervals. We also describe the stretched exponential form suggested for the distribution and the generation of the surrogate records. Section IV deals with the moments of the return intervals. We quantify the deviation from the scaling that exhibits multiscaling behavior. We simulate the return intervals with different sizes and show the finite size effect for long \( \langle \tau \rangle \). We also study the discreteness effect for short \( \langle \tau \rangle \) and explore the relation between the moment and its order. In Sec. V we present a discussion.

II. DATABASE

We analyze the Trades And Quotes (TAQ) database from New York Stock Exchange (NYSE), which records every trade for all the securities in United States stock markets. The duration is from Jan. 1, 2001 to Dec. 31, 2002, which has a total of 500 trading days. We study all 500 companies which consist of Standard & Poor’s 500 index (S&P 500) [43], the benchmark for American stock markets. The vola-
tility is defined the same as in [24]. First we take the absolute value for the logarithmic price change, then remove the intraday U-shape pattern, and finally normalize it with the standard deviation. Here the price is the closest tick to a minute mark. Thus the sampling time is 1 min and a trading day usually has 391 points after removing the market closing hours. For each stock, the size of data set is about 200 000 records.

III. SCALING IN RETURN INTERVALS

The probability density function (PDF) for the return intervals $\tau$ of the financial volatilities is well-approximated by the following form:

$$P_q(\tau) = \frac{1}{\langle \tau \rangle} f(\langle \tau \rangle^q),$$

(1)

as analyzed by Yamasaki et al. [23] and Wang et al. [24,25]. Here $\langle \cdot \rangle$ stands for the average over the data set and mean interval $\langle \tau \rangle$ depends on the threshold $q$. It was suggested that the scaling function can be approximated by a stretched exponential [23–25],

$$f(x) = ce^{-(ax)^y},$$

(2)

for financial records, which is consistent with other long-term correlated records [26–29]. Here $a$ and $c$ are fitting parameters and $y$ is the exponent characterizing the long-term correlation [26–29]. From the normalization of PDF follows [44]

$$1 = \int_0^\infty P_q(\tau)d\tau = \int_0^\infty \frac{1}{\langle \tau \rangle} ce^{-a(\langle \tau \rangle^q)^y}d\tau.$$

(3)

From the definition of $\langle \tau \rangle$ follows

$$\langle \tau \rangle = \int_0^\infty \tau P_q(\tau)d\tau = \int_0^\infty \frac{1}{\langle \tau \rangle} ce^{-a(\langle \tau \rangle^q)^y}d\tau.$$

(4)

Using Eqs. (3) and (4), the parameters $a$ and $c$ can be expressed by $y$,

$$a = \Gamma(2/y)/\Gamma(1/y),$$

$$c = \gamma a/\Gamma(1/\gamma) = \gamma \Gamma(2/y)/\Gamma(1/y)^2.$$  

(5)

Here $\Gamma(a) = \int_0^\infty t^{a-1}e^{-t}dt$ is the Gamma function. Thus if the stretched exponential distribution is valid for the scaled interval $\tau/\langle \tau \rangle$, it is completely determined by $y$. For $y=1$, the record has no long-term correlations and the return interval distribution indeed follows an exponential distribution, represented by a Poissonian statistics, as expected.

Though the scaling in the return intervals distribution is a good approximation, we find slight deviations that as shown below are attributed to nonlinear features. To explicitly explore the quality of the scaling in return interval distributions, we study all S&P 500 constituents and show the results of four representative stocks: Citigroup (C), General Electric (GE), Coca Cola (KO), and Exxon Mobil (XOM). All other stocks studied here usually show similar features. First, we examine the cumulative distribution [45] of the scaled intervals,

$$D(\tau/\langle \tau \rangle) = \int_{\tau}^\infty P_q(\tau)d\tau = \int_{\tau/\langle \tau \rangle}^\infty f(x)dx.$$  

(6)

If the scaling function $f(\tau/\langle \tau \rangle)$ is valid, the cumulative distributions should also collapse to a single curve. Otherwise, the cumulative distributions, which integrate deviations, may show clearer deviations from scaling. Indeed, in Fig. 1 we show cumulative distributions for three thresholds $q=2$, 4, and 6. Note that the volatility is normalized by its standard deviation, the threshold $q$ is in units of standard deviations, and therefore $q=6$ is a quite large volatility. It is clearly seen that those distributions are close to each other but do not collapse to a single curve. More important, they show apparent deviations from the scaling, which are systematic with the threshold. For small scaled intervals $\tau/\langle \tau \rangle$, the cumulative distribution decreases with $q$, while for large scaled intervals $\tau/\langle \tau \rangle$, it increases with $q$ [46]. In other words, the scaled interval prefers to be larger for higher threshold. This systematic trend suggests multiscaling in the return intervals, which might be related to the nonlinear correlations in the volatility.

To better understand the systematic trends and test if it is not due to finite size effect or discreteness of minutes, we also measure the cumulative distribution of return intervals for surrogate records of volatilities using the Schreiber method [40–42] where nonlinearities are removed. For a given time series, we store the power spectrum and randomly

FIG. 1. (Color online) Cumulative distribution [45] of the scaled intervals $\tau/\langle \tau \rangle$ for stock C, GE, KO, XOM, and GE’s surrogate. Symbols are for three thresholds, $q=2$ (circles), 4 (squares), and 6 (triangles), respectively. As two examples, we fit the cumulative distribution of stock C ($q=2$) and the surrogate ($q=2$) to a stretched exponential distribution [Eq. (2)] with exponent $\gamma=0.25$ and $\gamma=0.50$ correspondingly. Except for stock C, all symbols and curves are vertically shifted for better visibility. For the surrogate records, symbols collapse almost perfectly to one curve. However, all original data exhibit similar systematic deviations from the scaling. This suggests that the nonlinear correlations in the volatility series affect the scaling in its return intervals.
shuffle the sequence, then we apply the following iterations. Each iteration consists of two consecutive steps:

(i) We perform the Fourier transform of the shuffled series, replace its power spectrum with the original one, then take the inverse Fourier transform to achieve a series. This step enforces the desired power spectrum to the series, while the distribution of volatilities usually is modified.

(ii) By ranking, we exchange the values of the resulting series from step (i) with that of the original record. The largest value in the resulting series is replaced by the largest one in the original series, the second largest value is replaced by the second largest one, and so on. This step restores the original distribution but now the power spectrum is changed.

To achieve the convergence to the desired power spectrum and distribution, we repeat these two steps 30 times. In this way, a “surrogate” series is generated. Because of the Wiener-Kinchine theorem [47], the surrogate record has the same linear correlations as the original, as well as the distribution. The only difference is that the original record has the nonlinear correlations (if they exist) but the surrogate does not have any nonlinear features.

In Fig. 1 we also plot the cumulative distribution for the surrogate with the same three thresholds as the original. Since the surrogate records lost the nonlinear correlations, they are similar to each other, we only show results for GE’s surrogate. It is seen that the collapse of the surrogate for different $q$ values is significantly better than that of the original and the deviation tendency with the threshold in the original records disappears. This indicates that the scaling deviations in the original are due to the nonlinear correlations in the volatility. To further test this hypothesis, we analyze the moments $\mu_m = \langle (\tau/\tau_0)^m \rangle^{1/m}$ in Sec. IV and show similar and consistent deviations from scaling. We also compare our results to the stretched exponential distribution (dashed lines). This curve is very close to the empirical results, in particular for the surrogate records which contain only the linear correlations. This suggests that PDF of return intervals is well approximated by a stretched exponential.

IV. THE MOMENTS OF SCALED INTERVALS

The cumulative distribution shows a clear systematic trend with $q$, which is difficult to see from the PDF directly [23–28]. To further analyze the systematic tendency in the distribution, we calculate the moments $\mu_m$ averaged over a stock data set as a function of $\langle \tau \rangle$, where a mean interval $\langle \tau \rangle$ corresponds to a threshold $q$ and therefore characterizes a return interval series. We study moments for a wide range of $\langle \tau \rangle$, from 3 min (to avoid the artificial effects due to discreteness close to $\tau=1$) to thousands of minutes (a few trading days or even a week). Assuming a single scaling function for the PDF $P_\theta(\tau)$, Eq. (1), it follows that

$$\mu_m = \langle (\tau/\tau_0)^m \rangle^{1/m} = \left\{ \int_0^\infty \frac{1}{\langle \tau \rangle} f(\tau/\tau_0)d\tau \right\}^{1/m} = \left\{ \int_0^\infty x^m f(x)dx \right\}^{1/m},$$

which only depends on $m$ and on the form of the scaling function $f(x)$ but independent of $\langle \tau \rangle$. Thus if $\mu_m$ depends on $\langle \tau \rangle$, it suggests deviation from the assumption of scaling.

A. Moments vs mean interval $\langle \tau \rangle$

First we examine the relation between the moments $\mu_m$ and the mean interval $\langle \tau \rangle$. Figure 2 shows four representative moments $m=0.25, 0.5, 2,$ and 4 for stocks C, GE, KO, and XOM. Ignoring small fluctuations, which is usually due to limited size data, all moments $\mu_m$ for the original records deviate significantly from a horizontal line, which is expected for a perfect scaling of the PDF. They depend on $\langle \tau \rangle$ and show some systematic tendency. For $m > 1$, moments have similar convex structure, first $\mu_m$ increases with $\langle \tau \rangle$ and then decreases, whereas the crossover starts earlier for larger $m$. For $m < 1$, moments also show a similar tendency but in the opposite direction compared to $m > 1$. These deviations from scaling in $\mu_m$ are consistent with the deviations seen in the cumulative distributions shown in Fig. 1. Moments of large $m$ ($m > 1$) represent large $\tau/\langle \tau \rangle$ in the PDF and they initially (for $\langle \tau \rangle \approx 100$) increase with $\langle \tau \rangle$ ($\langle \tau \rangle$ increases with the threshold $q$), while moments of small $m$ ($m < 1$) represent small $\tau/\langle \tau \rangle$ and they initially (for $\langle \tau \rangle \approx 100$) decrease with $\langle \tau \rangle$.

To further test if the systematic deviations are not due to finite size effects and discreteness, we also examine moments for the surrogate records which are more flat for most ranges, as shown in Fig. 2. For the same order $m$, the moment of the surrogate obviously differs from that of the original, especially in the medium range of $\langle \tau \rangle$ ($10 < \langle \tau \rangle \leq 100$). This discrepancy suggests that the nonlinear correlations ex-

FIG. 2. (Color online) Moment $\mu_m$ for the scaled intervals of stock C, GE, KO, and XOM. We show results from the original volatility series (filled symbols) and their surrogate (empty symbols). For each case, four moments, $m=0.25$ (circles), 0.5 (squares), 2 (diamonds), and 4 (triangles), are demonstrated. Symbols for the original are clearly away from the horizontal line and their deviations are much larger than that of surrogate, therefore the nonlinear correlations in the original are related to those deviations. To avoid effects from the resolution and size limit, we choose the shadow area, $10 < \langle \tau \rangle \leq 100$ (corresponding to $1.6 < q \leq 4.2$ for the 500 stocks), to study the multiscaling behavior.

First we examine the relation between the moments $\mu_m$ and the mean interval $\langle \tau \rangle$. Figure 2 shows four representative moments $m=0.25, 0.5, 2,$ and 4 for stocks C, GE, KO, and XOM. Ignoring small fluctuations, which is usually due to limited size data, all moments $\mu_m$ for the original records deviate significantly from a horizontal line, which is expected for a perfect scaling of the PDF. They depend on $\langle \tau \rangle$ and show some systematic tendency. For $m > 1$, moments have similar convex structure, first $\mu_m$ increases with $\langle \tau \rangle$ and then decreases, whereas the crossover starts earlier for larger $m$. For $m < 1$, moments also show a similar tendency but in the opposite direction compared to $m > 1$. These deviations from scaling in $\mu_m$ are consistent with the deviations seen in the cumulative distributions shown in Fig. 1. Moments of large $m$ ($m > 1$) represent large $\tau/\langle \tau \rangle$ in the PDF and they initially (for $\langle \tau \rangle \approx 100$) increase with $\langle \tau \rangle$ ($\langle \tau \rangle$ increases with the threshold $q$), while moments of small $m$ ($m < 1$) represent small $\tau/\langle \tau \rangle$ and they initially (for $\langle \tau \rangle \approx 100$) decrease with $\langle \tau \rangle$.

To further test if the systematic deviations are not due to finite size effects and discreteness, we also examine moments for the surrogate records which are more flat for most ranges, as shown in Fig. 2. For the same order $m$, the moment of the surrogate obviously differs from that of the original, especially in the medium range of $\langle \tau \rangle$ ($10 < \langle \tau \rangle \leq 100$). This discrepancy suggests that the nonlinear correlations ex-
ist in the original volatility and accounts for the scaling deviations. Nevertheless, all moments of surrogate show small curvature from a perfect straight line at both short and long $\langle \tau \rangle$, which are much weaker compared to the original records. The weak curvature suggests that some additional effects, not related to the nonlinear correlations, affect the moments. For small $\langle \tau \rangle$, the resolution discrete limit seems to have some influence on the moments. We will discuss this effect in Sec. IV C. For large $\langle \tau \rangle$, the moments are gradually approaching the horizontal line and are more fluctuating, the effect seems to be related to limited size of the record. On the other hand, for moments of high order such as $m=4$, the trend in the medium range is not as obvious as for the lower order moments. This is probably due to a lack of statistics for high order moments. This effect will be discussed further in Sec. IV B.

B. Multiscaling

For the original volatility records, the systematic tendency in the distribution of $\tau$ and the moments implies that the return intervals may have multiscaling features. To avoid as much as possible the effect of discreteness and finite size, we calculate the moments only for some medium range of $\langle \tau \rangle$ where the effects are small. Since there is no nonlinear correlations in the surrogate records, the curvature in their moments is only due to the additional effects, we use the surrogate curve as our reference. For small $\langle \tau \rangle$, the increasing (decreasing) range for $m>1$ ($m<1$) almost ends at $\langle \tau \rangle =10$ min. For large $\langle \tau \rangle$, the curves start to decrease (increase) from different positions, but at $\langle \tau \rangle=100$, all curves do not or just start to decrease (increase). Thus we choose to study $\mu_n$ in the region, $10<\langle \tau \rangle \leq 100$, represented by the shadow areas in Fig. 2. Note that a certain $\langle \tau \rangle$ represents a certain threshold $q$. For the 500 constituent stocks of S&P 500, $\langle \tau \rangle=10$ corresponds to $q=1.6 \pm 0.2$ and $\langle \tau \rangle=100$ corresponds to $q=4.2 \pm 0.3$. In this range, we find a clear trend for the original records while the surrogate is almost horizontal. To quantify the tendency, we fit the moments with a power-law,

$$\mu_m \sim \langle \tau \rangle^\alpha.$$  

If the distribution of $\tau/\langle \tau \rangle$ follows a scaling law, the exponent $\alpha$ should be some value very close to 0. If $\alpha$ is significantly different from 0, it suggests multiscaling.

To examine the multiscaling behavior for the whole market, we calculate $\alpha$ for all 500 stocks of S&P 500 constituents and plot the histogram for $m=0.25$ to 2. Figure 3 shows that each histogram has a narrow distribution, which suggests that $\alpha$ are similar for the 500 stocks. For the original records, almost all $\alpha$ significantly differ from 0, thus the moments clearly depend on the mean interval. Moreover, the mean value of $\alpha$ shifts with order $m$ from $\langle \alpha \rangle= -0.22 \pm 0.08$ for $m=0.25$ to $\langle \alpha \rangle= 0.08 \pm 0.05$ for $m=2$ which means the dependence varies with the order $m$. This behavior suggests multiscaling in the return intervals distribution. Indeed, histograms for the surrogate records are more centered around values close to $\alpha=0$ (from $\langle \alpha \rangle= -0.07 \pm 0.04$ for $m=0.25$ to $\langle \alpha \rangle= 0.08 \pm 0.05$ for $m=2$) which means the dependence varies with the order $m$. This behavior suggests multiscaling in the return intervals distribution. Indeed, histograms for the surrogate records are more centered around values close to $\alpha=0$ (from $\langle \alpha \rangle= -0.07 \pm 0.04$ for $m=0.25$ to $\langle \alpha \rangle= 0.08 \pm 0.05$ for $m=2$) which means the dependence varies with the order $m$. This behavior suggests multiscaling in the return intervals distribution.

C. Discreteness effect

For small $\langle \tau \rangle$ ($\langle \tau \rangle \leq 10$), the behavior of $\mu_m$ as a function of $\langle \tau \rangle$ was attributed to the discreteness. Here we examine
FIG. 4. (Color online) Dependence of average multiscaling exponent ⟨α⟩ on order m. The average ⟨α⟩ was taken over the 500 α of the S&P 500 constituents. The error bars are standard deviations over the 500 α. Results for the original (circles) and surrogate records (squares) are displayed. For large m, the two curves have a similar tendency which is attributed to the finite size effects. For small m, the two curves are significantly different which supports the multiscaling in the return intervals, due to the nonlinear correlations in the original volatility. The inset demonstrates ⟨α⟩ averaged over 500 stretched exponential distributed i.i.d. simulations with γ=0.3. Three sizes, 2×10⁶, 2×10⁵, and 2×10⁴ are displayed, which clearly shows the finite size effect.

better resolution, since the return intervals has the multiscaling behavior, as shown for larger ⟨τ⟩ in the range 10⟨τ⟩ ≤ 100 which is not affected by discreteness.

D. Moments vs order m

The moments μₘ have systematic dependence on m, as seen in Figs. 2 and 3 where the moments are plotted as the function of ⟨τ⟩. It is of interest to explore the relation between the moments and m directly. For a fixed ⟨τ⟩, representing a given threshold q, one can study the return intervals and their moments of various orders which exhibit information on different scales of τ. Moments of large m represent large τ and vice versa. If τ/⟨τ⟩ follows a single distribution without corrections due to effects such as discreteness and finite size, curves of μₘ vs m for different ⟨τ⟩ should collapse to a single one, which only depends on the scaling function f(x) from Eq. (7). In Fig. 6 we plot μₘ vs m for both the original and surrogate records. We plot μₘ for m between 0.1 and 10 for three ⟨τ⟩ values: 10, 80, and 400 min. For the original [Fig. 6(a)], there is substantial deviations from a single curve. This supports our suggestion that the return intervals has multiscaling behavior. Moments for the surrogate [Fig. 6(b)] converge to a single curve for m≤2 but become diverse for high orders, which agrees with the strong influence of the finite size effects. As a reference, we also plot the analytical moments [Fig. 6(c)] from the stretched exponential distribution. Substituting Eq. (2) into Eq. (7), we obtain

FIG. 5. (Color online) Discreteness effect in the moments. (a) Moments for stock GE with three resolutions, 1 (circles), 5 (squares), and 10 min (diamonds). Filled symbols are for m=0.5 while empty symbols are for m=2. (b) Moments of artificial records averaged over 100 simulations. For each trial, we simulate the return intervals which follow a stretched exponential distribution with γ=0.3 and the length of 200,000 points. Symbols are similar to that in (a). Three resolutions, 1, 5, and 10 time units are displayed. To show the disappearing of the discreteness, we also plot simulation results for continuous return intervals (triangles), which exhibit a constant moment, independent of ⟨τ⟩.
We study the scaling properties of the distribution of the volatility return intervals for all S&P 500 constituents. We find small but systematic deviations from scaling assumption with the threshold $q$ in the cumulative distribution. Compared to the good collapse for the surrogate records where nonlinearities are removed, this suggests that the origin of this trend is due to nonlinear correlations in the original volatility. The nonlinearities in the volatilities may originate from the nonlinear interactions between the many market participants [48,49]. Moreover, we find similar systematic deviations for the moments $\mu_m$ which are also attributed to the nonlinear correlations in the volatility. We distinguish these deviations from the deviations due to the discreteness for small $\langle \tau \rangle$ and finite size effect for large $\langle \tau \rangle$. Further, we explore the dependence of the moment $\mu_m$ on its order $m$. When compared to surrogate records and to analytical curves, the results support the multiscaling hypothesis of the return intervals. Thus the scaling assumption in the return interval distributions, although it is a good approximation, cannot be exact. To further understand the volatility and its return intervals, we also tried to simulate them using theoretical models such as fractional Brownian motion and fractionally integrated generalized auto regressive conditional heteroscedasticity (FIGARCH) [50]. Also, the stretched exponential form of the scaling function can only be an approximation. Recently Eisler et al. [38,39] exhibited that the distribution of intertrade times has similar multiscaling behavior and the market activity depends on the company capitalization. It would be interesting to connect the intertrade times with the return intervals and test size dependence in the return intervals. The multiscaling behavior in the return intervals may be related to the different underlying mechanisms on different time scales. The behavior on different stocks may reflect those mechanics differently therefore a comprehensive examination on many companies provides another view on the multiscaling.

Note that for very large scaled intervals, the cumulative distribution becomes linear. For instance, for \( q = 2 \), the corresponding minimum is \( 1/\langle \tau \rangle = 0.1 \). For higher \( q \) such as \( q = 6 \), \( \langle \tau \rangle = 347 \) and the minimum \( 1/\langle \tau \rangle = 0.003 \) is even smaller.

In this paper the cumulative distribution of the return intervals is actually the complementary cumulative distribution. For simplicity we call it “cumulative distribution.”

Note that for very large scaled intervals, \( \tau/\langle \tau \rangle \gg 1 \), the curves have apparent fluctuations, which cannot be trusted as much as that of smaller scaled intervals, due to poor statistics.

Here we assume that the scaled interval \( \tau/\langle \tau \rangle \) is continuous. This assumption is not precisely accurate since the return intervals are discrete. However, the minimum scaled interval usually is not very large. For example, \( \langle \tau \rangle = 9.8 \) for GE return interval of \( q = 2 \), the corresponding minimum is \( 1/\langle \tau \rangle = 0.1 \). For higher \( q \) such as \( q = 6 \), \( \langle \tau \rangle = 347 \) and the minimum \( 1/\langle \tau \rangle = 0.003 \) is even smaller.
